# 1 Installation

### 1.1 Download/Install R

Go to <a href="https://www.r-project.org/">https://www.r-project.org/</a> and follow the download and installation instructions provided.

### 1.2 (Recommended) Download/Install R Studio

Go to <a href="https://www.rstudio.com/products/rstudio/download/">https://www.rstudio.com/products/rstudio/download/</a> and follow the download and installation instructions provided.

# 1.3 Download App Files from Github

Go to <a href="https://github.com/stefangraw/Allocation-Power-Optimizer">https://github.com/stefangraw/Allocation-Power-Optimizer</a> and click "Clone or download" and choose Download ZIP. Once all files are downloaded, extract the main folder. Open the extracted folder and load the R script entitled "shiny-apo.R" with R Studio (or R if R Studio was not installed).

### 1.4 Install Required R Packages

Open R Studio (or the R console if R Studio was not installed) and type the following (ignore >>):

>> install.packages("shiny")

>> install.packages("shinyjs")

### 1.5 Run Application

In the top-right corner of the scripting window of R Studio, click "Run App". If R Studio was not installed, enter the following command into the R console (ignore >>):

>> runApp('.../shiny-apo.R')

Where "..." denotes the path to the file "shiny-apo.R".

A new window should now appear entitled "Allocation & Power Optimizer". For visibility we suggest maximizing the window.

# 2 Explanation of Inputs

#### 2.1 Basic Inputs

# 2.1.1 Critical value $\alpha$

This is the type I error rate desired, or the probability of failing to reject the null hypothesis when it is true. Typical values of  $\alpha$  are 0.01, 0.05, and 0.10.

#### 2.1.2 Total sample size

The total number of subjects available (or estimated to be available) for this study. Higher values result in more power, but may not be reasonably attainable.

#### 2.1.3 Effect size as

This determines the effect size of the treatment arms. Arm 1 is always the control arm and has effect size of 0. If either "Best arm" or "Linear trend" is selected, then the user will need to also give the

number of arms (see 2.1.4) and the standardized effect size (see 2.1.5). Additionally, if either "Best arm" or "Linear trend" are selected, the effect sizes for each arm  $2, \dots, k-1$  under the alternative hypothesis  $H_1$ , are determined as follows: "Best arm" sets each arm's effect to 0 besides arm k, which has effect size equal to the selected standardized effect size (see 2.1.4). "Linear trend" has the effect sizes grow linearly from the control (effect of 0) to arm k (the best arm in this scenario, with effect of the selected standardized effect size). The linear function for calculating the effect of arm i is d(i-1)/(k-1) where d is the selected standardized effect size. Typically the linear trend scenario will have higher overall power but will be less likely to choose the "best" treatment arm.

If "Custom" is selected, then the user will need to enter each non-control arm's standardized effect size manually (see 2.1.6). Note that it is possible to use "Custom" to recreate "Linear trend" and/or "Best arm" schemes.

#### 2.1.4 Number of arms

The number of treatment arms k (including control) for the trial. The first arm is always assumed to be the control arm. For example, if you have 5 treatment arms and 1 control arm, you have a total of 6 arms and would input 6 here. Only necessary if not using "Custom" Effect size as (see 2.1.3).

#### 2.1.5 Standardized effect size

The standardized effect size of arm k, relative to the control arm's standardized effect size of 0. This is used only when "Best arm" or "Linear trend" is selected for Effect size as (see 2.1.3). Mathematically, this is the number of standard deviations by which the best treatment outperforms the control arm, on average. This is the effect size assuming the data has been standardized to have a sample variance of 1. Typically this value comes from pilot data, or what the researcher feels is the "minimum improvement vs the control that has meaning". For more information, the Wikipedia article on effect sizes provides a good overview of the topic <a href="https://en.wikipedia.org/wiki/Effect\_size">https://en.wikipedia.org/wiki/Effect\_size</a>, as do many introductory statistical textbooks.

### 2.1.6 $H_1$ treatment means (comma separated)

This is only available when using "Custom" Effect size as (see 2.1.3). This allows the user to specify the standardized effect size of each treatment arm, relative to the control arm's standardized effect size of 0. The control arm is always assumed to be 0 and implicitly defined, so does not need to be entered in this field. One standardized effect size should be entered for each non-control treatment arm, separated by commas. For example, if one desires to recreate a linear trend for 4 total arms (3 treatment arms and 1 control arm), where the best arm has standardized effect size of 0.9, one would enter "0.3,0.6,0.9" (without the quotes) in this field.

Note it is possible to enter effect sizes of 0 or even negative.

### 2.1.7 Number of cores/threads

This determines the number of simultaneous threads for parallel processing. More cores result in faster computation time. Using more cores than your computer has available may cause it to crash. This defaults to half of the maximum number of cores your computer has available.

### 2.1.8 Advanced settings

When checked, makes the Advanced settings available (see section 2.2).

#### 2.1.9 Go!

After setting inputs as desired, this runs the app to determine the operating characteristics of the design and maximize the power (see section 3).

#### 2.1.10 Show table

When checked, shows the estimated power, threshold, probability of early stopping, probability of choosing best treatment arm, and total sample size for various Stage 1 sample sizes. Note that this information is only available after the app has been run via the Go! Button (section 2.1.8). Also see 3.5.

### 2.2 Advanced Inputs

To view/change these, the "Advanced settings" box must be clicked (see 2.1.8).

### 2.2.1 Futility Stage I: $\delta$ and $\epsilon$

Allows for more advanced early stopping rules. Both  $\delta$  and  $\epsilon$  default to zero, meaning that if unchanged then the only early stopping rule will be if the arm chosen at the end of Stage 1 is the control arm. Input  $\delta$  defines the minimum number of standard deviations required for success between the arm chosen at the end of Stage 1 and the control arm. Input  $\epsilon$  determines the probability required to exceeding the threshold set by  $\delta$  at the end of Stage 1 (otherwise stop early for futility). If  $\delta$  is zero, then  $\epsilon$  defines the probability required for the winner arm to be superior to the control arm at the end of Stage 1 (otherwise stop early for futility).

### 2.2.2 Number of checked sample sizes

The number of combinations of Stage 1 and Stage 2 allocations to consider when attempting to optimize power. This can be fairly coarse (defaults to 20) and still produce good results. For m checked sample sizes, and for N total subjects, k treatment arms, and  $n_1$  patients allocated to each arm in Stage 1, the choices of  $n_1$  are chosen such that there are m equally spaced points between  $n_1=2$  and  $n_1=\frac{N}{k}-2$ .

#### 2.2.3 Post sample size

The number of draws to make from posterior distributions. Higher values of this will result in more accurate MCMC conclusions, but at the cost of computation time. This directly effects the accuracy of all operating characteristics.

#### 2.2.4 Simulation runs $H_0$

The number of times to simulate under the null hypothesis  $H_0$ : each arm has 0 effect, meaning each treatment is equivalent to the control arm. This directly effects the accuracy of calculating the threshold  $\tau$  for controlling the specified type I error rate  $\alpha$  (see 2.1.1). Higher values of this will result in more accurate estimations of  $\tau$  at the cost of computation time.

### 2.2.5 Simulation runs $H_1$

The number of times to simulate under the alternative hypothesis  $H_1$ , which is determined by inputs "Standardized effect size" and "Effect size as" (see 2.1.3 – 2.1.6). This directly effects the accuracy of calculating the statistical power of the trial (the probability of trial success given  $H_1$  is true). Higher values of this will result in more accurate power estimations at the cost of computation time.

### 2.2.6 Random seed

Allows the user to use a randomly generated seed or input a seed, for reproducibility of results. If a random seed is chosen, the value will be output in the Log of inputs (see 3.4).

# 3 Explanation of Outputs

# 3.1 Graph: Stage 2 Rejection Threshold

This shows the estimated threshold  $\tau$  used to control the type I error rate  $\alpha$  for various choices of  $n_1$  (the number of subjects allocated per arm in Stage 1). The smooth blue line is the smoothed fit (smoothed quartic polynomial splines and a single knot) and is used to compute the power. The number of points on this graph is directly controlled by the "Post sample size" input (see 2.2.3). If the red line connecting the points is especially chaotic, we recommend increasing the advanced inputs "Post sample size" and "Simulation runs  $H_0$ ) (see 2.2.3 and 2.2.4).

### 3.2 Graph: Overall Power

This shows the estimated statistical power for various choices of  $n_1$  (the number of subjects allocated per arm in Stage 1). The smooth blue line is the smoothed fit (smoothed via cubic spline) and is used to compute the power. The number of points on this graph is directly controlled by the "Post sample size" input (see 2.2.3). If the red line connecting the points is especially chaotic, we recommend increasing the advanced inputs "Post sample size" and "Simulation runs  $H_1$ ) (see 2.2.3 and 2.2.5). The vertical dashed line represents the choice of  $n_1$  which maximizes the statistical power.

# 3.3 Table of Power for Adaptive, Bonferroni-adjusted, and Best arm known Designs

### 3.3.1 Adaptive design

This design is the adaptive Bayesian two-stage drop-the-losers design. This row shows the power under the optimal choice of  $n_1$  (see 3.2), the choice of  $n_1$  and  $n_2$  that give this optimal power, the total subjects actually use (may be slightly less than what is inputted as Total sample size (see 2.1.3) due to rounding), and the associated  $\tau$  which is the threshold for trial success that controls the type I error rate specified by Critical value  $\alpha$  (see 2.1.1). Additionally shown is the probability of early stop due to futility, which might depend on some advanced options (see 2.2.1), and the probability successfully completing the trial with the best treatment arm being chosen as the winner in Stage 1 (defined as the treatment arm with largest standardized effect size, see 2.1.3-2.1.6. If multiple arms would be considered the best treatment arm, a successful trial that used any of them as the winner counts toward success with the best arm).

# 3.3.2 Bonferroni adjusted t

The standard Bonferroni-adjusted design is assumed to be k-1 independent T tests between each treatment arm and the control, each with critical value  $\alpha/(k-1)$ . The overall power of the standard test is then  $1-\prod_{i=2}^k(1-\mathcal{P}_i)$  where  $\mathcal{P}_i$  is the power of the T test between treatment i and the control arm at the  $\alpha/(k-1)$  level. This represents the lower bound of the power. Note that as this is a single stage design, there is no potential to stop early for futility.

#### 3.3.3 If best arm known

This design assumes the best arm (typically arm k unless using "Custom" Effect size as, see 2.1.3) is known. In this case, the best design is to assign N/2 patients to the best arm and control, and then perform a T test. The power of such a test for the inputs given is outputted here, and represents the upper bound of the power. Note that as this is a single stage design, there is no potential to stop early for futility.

### 3.4 Log of inputs

This is a log of inputs (see 2.1 and 2.2) which can be copy/pasted so that the same analyses may be rerun. The random seed selected is also outputted, along with the run time.

#### 3.5 Show table

After the app has run and outputs are displayed, clicking this box shows a table displaying, for various choices of  $n_1$ , the estimated power,  $n_2$ , N,  $\tau$ , probability of stopping early for futility, and probability of successful trial where the best treatment arm is selected as the winner in Stage 1. The best treatment arm is defined as the arm with the largest standardized effect size (see 2.1.3-2.1.6). If multiple arms would be considered the best treatment arm, a successful trial that used any of them as the winner counts toward success with the best arm. The table may be sorted by any of these columns.

# 4 Mathematical Notation and Definitions

#### $4.1 \quad \alpha$

The type I error rate (see 2.1.1).

### 4.2 k

The number of treatment arms (see 2.1.2).

#### 4.3 *N*

The total number of subjects available, equal to  $N=kn_1+2n_2$  (see 2.1.3).

### 4.4 $n_1$ and $n_2$

The number of patients assigned to each arm in Stage 1 and Stage 2 of the design, respectively.

#### 4.5 d

The standardized effect size (see 2.1.4). Equivalent to Cohen's d.

#### 4.6 au

The threshold for trial success, typically chosen to preserve the type I error rate  $\alpha$ . In other words, the trial succeeds only if at the end of Stage 2 it is true that the probability that the best arm is better than the control arm exceeds  $\tau$ .
